<sup>1</sup>Course MATH-GA.2043 or CSCI-GA.2112, Fall 2020

October 29, 2020

# Outline

- 1 Fourier Series
- 2 Discrete Fourier Transform
- 3 Fast Fourier Transform
- 4 Applications of FFT
- 5 Wavelets
- 6 Conclusions

# Fourier Composition

# Fourier Decomposition

# Periodic Functions

- Consider now interpolating / approximating **periodic functions** defined on the interval  $I = [0, 2\pi]$ :

$$\forall x \quad f(x + 2\pi) = f(x),$$

as appear in practice when analyzing signals (e.g., sound/image processing).

- Also consider only the space of complex-valued **square-integrable functions**  $L^2_{2\pi}$ ,

$$\forall f \in L^2_w : \quad (f, f) = \|f\|^2 = \int_0^{2\pi} |f(x)|^2 dx < \infty.$$

- Polynomial functions are not periodic and thus basis sets based on orthogonal polynomials are not appropriate.
- Instead, consider sines and cosines as a basis function, combined together into **complex exponential functions**

$$\phi_k(x) = e^{ikx} = \cos(kx) + i \sin(kx), \quad k = 0, \pm 1, \pm 2, \dots$$

# Fourier Basis Functions

$$\phi_k(x) = e^{ikx}, \quad k = 0, \pm 1, \pm 2, \dots$$

- It is easy to see that these are **orthogonal** with respect to the continuous dot product

$$(\phi_j, \phi_k) = \int_{x=0}^{2\pi} \phi_j(x) \phi_k^*(x) dx = \int_0^{2\pi} \exp[i(j-k)x] dx = 2\pi \delta_{ij}$$

- The complex exponentials can be shown to form a complete **trigonometric polynomial basis** for the space  $L_{2\pi}^2$ , i.e.,

$$\forall f \in L_{2\pi}^2 : \quad f(x) = \sum_{k=-\infty}^{\infty} \hat{f}_k e^{ikx},$$

where the **Fourier coefficients** can be computed for any **frequency** or **wavenumber**  $k$  using:

$$\hat{f}_k = \frac{(f, \phi_k)}{2\pi} = \frac{1}{2\pi} \cdot \int_0^{2\pi} f(x) e^{-ikx} dx.$$

# Fourier Decomposition

# Truncated Fourier Basis

- For a general interval  $[0, X]$  the **discrete frequencies** are

$$k = \frac{2\pi}{X}\kappa \quad \kappa = 0, \pm 1, \pm 2, \dots$$

- For non-periodic functions one can take the limit  $X \rightarrow \infty$  in which case we get **continuous frequencies**.
- Now consider a **discrete Fourier basis** that only includes the first  $N$  basis functions, i.e.,

$$\begin{cases} k = -(N-1)/2, \dots, 0, \dots, (N-1)/2 & \text{if } N \text{ is odd} \\ k = -N/2, \dots, 0, \dots, N/2 - 1 & \text{if } N \text{ is even,} \end{cases}$$

and for simplicity we focus on  $N$  odd.

- The least-squares **spectral approximation** for this basis is:

$$f(x) \approx \phi(x) = \sum_{k=-(N-1)/2}^{(N-1)/2} \hat{f}_k e^{ikx}.$$

# Discrete Fourier Basis

- Let us discretize a given function on a set of  $N$  **equi-spaced nodes** as a vector

$$\mathbf{f}_j = f(x_j) \quad \text{where} \quad x_j = jh \quad \text{and} \quad h = \frac{2\pi}{N}.$$

Observe that  $j = N$  is the same node as  $j = 0$  due to periodicity so we only consider  $N$  instead of  $N + 1$  nodes.

- Now consider a **discrete Fourier basis** that only includes the first  $N$  basis functions, i.e.,

$$\begin{cases} k = -(N-1)/2, \dots, 0, \dots, (N-1)/2 & \text{if } N \text{ is odd} \\ k = -N/2, \dots, 0, \dots, N/2 - 1 & \text{if } N \text{ is even.} \end{cases}$$

- Focus on  $N$  odd and denote  $K = (N-1)/2$ .
- Discrete dot product** between discretized “functions”:

$$\mathbf{f} \cdot \mathbf{g} = h \sum_{j=0}^{N-1} f_j g_j^*$$

# Fourier Interpolant

$$\forall f \in L^2_{2\pi} : \quad f(x) = \sum_{k=-\infty}^{\infty} \hat{f}_k e^{ikx}$$

- We will try to approximate periodic functions with a **truncated Fourier series**:

$$f(x) \approx \phi(x) = \sum_{k=-K}^K \phi_k(x) = \sum_{k=-K}^K \hat{f}_k e^{ikx}.$$

- The discrete Fourier basis is  $\{\phi_{-K}, \dots, \phi_K\}$ ,

$$(\phi_k)_j = \exp(ikx_j),$$

and it is a **discretely orthonormal basis** in which we can represent periodic functions,

$$\phi_k \cdot \phi_{k'} = 2\pi \delta_{k,k'}$$

# Proof of Discrete Orthogonality

The case  $k = k'$  is trivial, so focus on

$$\phi_k \cdot \phi_{k'} = 0 \text{ for } k \neq k'$$

$$\sum_j \exp(ikx_j) \exp(-ik'x_j) = \sum_j \exp[i(\Delta k)x_j] = \sum_{j=0}^{N-1} [\exp(ih(\Delta k))]^j$$

where  $\Delta k = k - k'$ . This is a geometric series sum:

$$\phi_k \cdot \phi_{k'} = \frac{1 - z^N}{1 - z} = 0 \text{ if } k \neq k'$$

since  $z = \exp(ih(\Delta k)) \neq 1$  and  
 $z^N = \exp(ihN(\Delta k)) = \exp(2\pi i(\Delta k)) = 1.$

# Fourier Matrix

- Let us collect the discrete Fourier basis functions as columns in a **unitary**  $N \times N$  **matrix** (`fft(eye(N))` in MATLAB)

$$\Phi_N = [\phi_{-K} | \dots | \phi_0 | \dots | \phi_K] \Rightarrow \Phi_{jk}^{(N)} = \frac{1}{\sqrt{N}} \exp(2\pi ijk/N)$$

- The truncated Fourier series is

$$\mathbf{f} = \Phi_N \hat{\mathbf{f}}.$$

- Since the matrix  $\Phi_N$  is unitary, we know that  $\Phi_N^{-1} = \Phi_N^*$  and therefore

$$\hat{\mathbf{f}} = \Phi_N^* \mathbf{f},$$

which is nothing more than a change of basis!

# Discrete Fourier Transform

- The **Fourier interpolating polynomial** is thus easy to construct

$$\phi_N(x) = \sum_{k=-(N-1)/2}^{(N-1)/2} \hat{f}_k^{(N)} e^{ikx}$$

where the **discrete Fourier coefficients** are given by

$$\hat{f}_k^{(N)} = \frac{\mathbf{f} \cdot \boldsymbol{\phi}_k}{2\pi} = \frac{1}{N} \sum_{j=0}^{N-1} f(x_j) \exp(-ikx_j) \approx \hat{f}_k$$

- We can make the expressions more symmetric if we shift the frequencies to  $k = 0, \dots, N$ , but one should still think of half of the frequencies as “negative” and half as “positive”.  
See MATLAB’s functions *fftshift* and *ifftshift*.

# Discrete Fourier Transform

- The **Discrete Fourier Transform** (DFT) is a change of basis taking us from real/time to Fourier/frequency domain:

$$\text{Forward } \mathbf{f} \rightarrow \hat{\mathbf{f}} : \quad \hat{f}_k = \frac{1}{\sqrt{N}} \sum_{j=0}^{N-1} f_j \exp\left(-\frac{2\pi i j k}{N}\right), \quad k = 0, \dots, N-1$$

$$\text{Inverse } \hat{\mathbf{f}} \rightarrow \mathbf{f} : \quad f_j = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} \hat{f}_k \exp\left(\frac{2\pi i j k}{N}\right), \quad j = 0, \dots, N-1$$

- There is **different conventions** for the DFT depending on the interval on which the function is defined and placement of factors of  $N$  and  $2\pi$ .  
Read the documentation to be consistent!
- A **direct** matrix-vector multiplication algorithm therefore takes  $O(N^2)$  multiplications and additions. **Can we do it faster?**

# Discrete spectrum

- The set of discrete Fourier coefficients  $\hat{\mathbf{f}}$  is called the **discrete spectrum**, and in particular,

$$S_k = \left| \hat{f}_k \right|^2 = \hat{f}_k \hat{f}_k^*,$$

is the **power spectrum** which measures the frequency content of a signal.

- If  $f$  is real, then  $\hat{f}$  satisfies the **conjugacy property**

$$\hat{f}_{-k} = \hat{f}_k^*,$$

so that half of the spectrum is redundant and  $\hat{f}_0$  is real.

- For an even number of points  $N$  the largest frequency  $k = -N/2$  does not have a conjugate partner.

# Approximation error: Analytic

- If  $f(t = x + iy)$  is **analytic** in a half-strip around the real axis of half-width  $\alpha$  and bounded by  $|f(t)| < M$ , then

$$\left| \hat{f}_k \right| \leq M e^{-\alpha |k|}.$$

- Then the Fourier interpolant is **spectrally-accurate**

$$\|f - \phi\|_{\infty} \leq 4 \sum_{k=n+1}^{\infty} M e^{-\alpha k} = \frac{2M e^{-\alpha n}}{e^{\alpha} - 1} \quad (\text{geometric series sum})$$

- The Fourier interpolating trigonometric polynomial is spectrally accurate and a really great approximation for (very) smooth functions.

# Spectral Accuracy (or not)

- The Fourier interpolating polynomial  $\phi(x)$  has **spectral accuracy**, i.e., exponential in the number of nodes  $N$

$$\|f(x) - \phi(x)\| \sim e^{-N}$$

for **sufficiently smooth functions**.

- Specifically, what is needed is sufficiently **rapid decay of the Fourier coefficients** with  $k$ , e.g., exponential decay  $|\hat{f}_k| \sim e^{-|k|}$ .
- Discontinuities cause slowly-decaying Fourier coefficients, e.g., power law decay  $|\hat{f}_k| \sim k^{-1}$  for **jump discontinuities**.
- Jump discontinuities lead to slow convergence of the Fourier series for non-singular points (and no convergence at all near the singularity), so-called **Gibbs phenomenon** (ringing):

$$\|f(x) - \phi(x)\| \sim \begin{cases} N^{-1} & \text{at points away from jumps} \\ \text{const.} & \text{at the jumps themselves} \end{cases}$$

# Gibbs Phenomenon

# Gibbs Phenomenon

# Aliasing

If we sample a signal at too few points the Fourier interpolant may be wildly wrong: **aliasing** of frequencies  $k$  and  $2k, 3k, \dots$

Standard anti-aliasing rule is the **Nyquist–Shannon** criterion (theorem):  
Need **at least 2 samples per period**.

## DFT

- Recall the transformation from real space to frequency space and back:

$$\mathbf{f} \rightarrow \hat{\mathbf{f}} : \quad \hat{f}_k = \frac{1}{N} \sum_{j=0}^{N-1} f_j \exp \left( -\frac{2\pi i j k}{N} \right), \quad k = -\frac{(N-1)}{2}, \dots, \frac{(N-1)}{2}$$

$$\hat{\mathbf{f}} \rightarrow \mathbf{f} : \quad f_j = \sum_{k=-(N-1)/2}^{(N-1)/2} \hat{f}_k \exp \left( \frac{2\pi i j k}{N} \right), \quad j = 0, \dots, N-1$$

- We can make the forward-reverse **Discrete Fourier Transform** (DFT) more symmetric if we shift the frequencies to  $k = 0, \dots, N$ :

$$\text{Forward } \mathbf{f} \rightarrow \hat{\mathbf{f}} : \quad \hat{f}_k = \frac{1}{\sqrt{N}} \sum_{j=0}^{N-1} f_j \exp \left( -\frac{2\pi i j k}{N} \right), \quad k = 0, \dots, N-1$$

$$\text{Inverse } \hat{\mathbf{f}} \rightarrow \mathbf{f} : \quad f_j = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} \hat{f}_k \exp \left( \frac{2\pi i j k}{N} \right), \quad j = 0, \dots, N-1$$

## FFT

- We can write the transforms in matrix notation:

$$\hat{\mathbf{f}} = \frac{1}{\sqrt{N}} \mathbf{U}_N \mathbf{f}$$

$$\mathbf{f} = \frac{1}{\sqrt{N}} \mathbf{U}_N^* \hat{\mathbf{f}},$$

where the **unitary Fourier matrix** is an  $N \times N$  matrix with entries

$$u_{jk}^{(N)} = \omega_N^{jk}, \quad \omega_N = e^{-2\pi i/N}.$$

- A **direct** matrix-vector multiplication algorithm therefore takes  $O(N^2)$  multiplications and additions.
- Is there a faster way to compute the **non-normalized**

$$\hat{f}_k = \sum_{j=0}^{N-1} f_j \omega_N^{jk} \quad ?$$

## FFT

- For now assume that  $N$  is even and in fact a power of two,  $N = 2^n$ .
- The idea is to split the transform into two pieces, **even and odd** points:

$$\sum_{j=2j'} f_j \omega_N^{jk} + \sum_{j=2j'+1} f_j \omega_N^{jk} = \sum_{j'=0}^{N/2-1} f_{2j'} (\omega_N^2)^{j'k} + \omega_N^k \sum_{j'=0}^{N/2-1} f_{2j'+1} (\omega_N^2)^{j'k}$$

- Now notice that

$$\omega_N^2 = e^{-4\pi i/N} = e^{-2\pi i/(N/2)} = \omega_{N/2}$$

- This leads to a **divide-and-conquer algorithm**:

$$\hat{f}_k = \sum_{j'=0}^{N/2-1} f_{2j'} \omega_{N/2}^{j'k} + \omega_N^k \sum_{j'=0}^{N/2-1} f_{2j'+1} \omega_{N/2}^{j'k}$$

$$\hat{f}_k = \mathbf{U}_N \mathbf{f} = (\mathbf{U}_{N/2} \mathbf{f}_{\text{even}} + \omega_N^k \mathbf{U}_{N/2} \mathbf{f}_{\text{odd}})$$

# FFT Complexity

- The **Fast Fourier Transform** algorithm is **recursive**:

$$FFT_N(\mathbf{f}) = FFT_{\frac{N}{2}}(\mathbf{f}_{\text{even}}) + \mathbf{w} \boxtimes FFT_{\frac{N}{2}}(\mathbf{f}_{\text{odd}}),$$

where  $w_k = \omega_N^k$  and  $\boxtimes$  denotes element-wise product. When  $N = 1$  the FFT is trivial (identity).

- To compute the whole transform we need  $\log_2(N)$  steps, and at each step we only need  $N$  multiplications and  $N/2$  additions at each step.
- The total **cost of FFT** is thus much better than the direct method's  $O(N^2)$ : **Log-linear**

$$O(N \log N).$$

- Even when  $N$  is not a power of two there are ways to do a similar **splitting** transformation of the large FFT into many smaller FFTs.
- Note that there are different **normalization conventions** used in different software.

# In MATLAB

- The forward transform is performed by the function  $\hat{f} = \text{fft}(f)$  and the inverse by  $f = \text{ifft}(\hat{f})$ . Note that  $\text{ifft}(\text{fft}(f)) = f$  and  $f$  and  $\hat{f}$  may be complex.
- In MATLAB, and other software, the frequencies are not ordered in the “normal” way  $-(N-1)/2$  to  $+(N-1)/2$ , but rather, the nonnegative frequencies come first, then the positive ones, so the “funny” ordering is

$$0, 1, \dots, (N-1)/2, \quad -\frac{N-1}{2}, -\frac{N-1}{2} + 1, \dots, -1.$$

This is because such ordering (shift) makes the forward and inverse transforms symmetric.

- The function *fftshift* can be used to order the frequencies in the “normal” way, and *ifftshift* does the reverse:

$$\hat{f} = \text{fftshift}(\text{fft}(f)) \text{ (normal ordering).}$$

# Multidimensional FFT

- DFTs and FFTs generalize straightforwardly to higher dimensions due to separability: **Transform each dimension independently**

$$\hat{f} = \frac{1}{N_x N_y} \sum_{j_y=0}^{N_y-1} \sum_{j_x=0}^{N_x-1} f_{j_x, j_y} \exp \left[ -\frac{2\pi i (j_x k_x + j_y k_y)}{N} \right]$$

$$\hat{\mathbf{f}}_{k_x, k_y} = \frac{1}{N_x} \sum_{j_y=0}^{N_y-1} \exp \left( -\frac{2\pi i j_y k_x}{N} \right) \left[ \frac{1}{N_y} \sum_{j_x=0}^{N_x-1} f_{j_x, j_y} \exp \left( -\frac{2\pi i j_x k_y}{N} \right) \right]$$

- For example, in two dimensions, **do FFTs of each column, then FFTs of each row of the result:**

$$\hat{\mathbf{f}} = \mathcal{F}_{row} (\mathcal{F}_{col} (\mathbf{f}))$$

- The cost is  $N_y$  one-dimensional FFTs of length  $N_x$  and then  $N_x$  one-dimensional FFTs of length  $N_y$ :

$$N_x N_y \log N_x + N_x N_y \log N_y = N_x N_y \log (N_x N_y) = N \log N$$

# Applications of FFTs

- Because FFT is a very fast, almost linear algorithm, it is used often to accomplish things that are not seemingly related to function approximation.
- Denote the Discrete Fourier transform, computed using FFTs in practice, with

$$\hat{\mathbf{f}} = \mathcal{F}(\mathbf{f}) \text{ and } \mathbf{f} = \mathcal{F}^{-1}(\hat{\mathbf{f}}).$$

- Plain FFT is used in signal processing for **digital filtering**: Multiply the spectrum by a filter  $\hat{S}(k)$  discretized as  $\hat{\mathbf{s}} = \left\{ \hat{S}(k) \right\}_k$ :

$$\mathbf{f}_{filt} = \mathcal{F}^{-1}(\hat{\mathbf{s}} \square \hat{\mathbf{f}}).$$

- Examples include **low-pass**, **high-pass**, or **band-pass filters**. Note that **aliasing** can be a problem for digital filters.

# FFT-based noise filtering (1)

```
Fs = 1000; % Sampling frequency
dt = 1/Fs; % Sampling interval
L = 1000; % Length of signal
t = (0:L-1)*dt; % Time vector
T=L*dt; % Total time interval

% Sum of a 50 Hz sinusoid and a 120 Hz sinusoid
x = 0.7*sin(2*pi*50*t) + sin(2*pi*120*t);
y = x + 2*randn(size(t)); % Sinusoids plus noise

figure(1); clf;
plot(t(1:100),y(1:100),'b--'); hold on
title('Signal Corrupted with Zero-Mean Random Noise')
xlabel('time')
```

# FFT-based noise filtering (2)

```

if (0)
    N=(L/2)*2; % Even N
    y_hat = fft(y(1:N));
    % Frequencies ordered in a funny way:
    f_funny = 2*pi/T* [0:N/2-1, -N/2:-1];
    % Normal ordering:
    f_normal = 2*pi/T* [-N/2 : N/2-1];
else
    N=(L/2)*2-1; % Odd N
    y_hat = fft(y(1:N));
    % Frequencies ordered in a funny way:
    f_funny = 2*pi/T* [0:(N-1)/2, -(N-1)/2:-1];
    % Normal ordering:
    f_normal = 2*pi/T* [-(N-1)/2 : (N-1)/2];
end

```

# FFT-based noise filtering (3)

```
figure(2); clf; plot(f_funny, abs(y_hat), 'ro'); hold
y_hat=fftshift(y_hat);
figure(2); plot(f_normal, abs(y_hat), 'b-');

title('Single-Sided Amplitude Spectrum of y(t)')
xlabel('Frequency (Hz)')

y_hat(abs(y_hat)<250)=0; % Filter out noise
y_filtered = ifft(ifftshift(y_hat));
figure(1); plot(t(1:100), y_filtered(1:100), 'r-')
```

# FFT results

# Spectral Derivative

- Consider approximating the derivative of a periodic function  $f(x)$ , computed at a set of  $N$  equally-spaced nodes,  $\mathbf{f}$ .
- One way to do it is to use the **finite difference approximations**:

$$f'(x_j) \approx \frac{f(x_j + h) - f(x_j - h)}{2h} = \frac{f_{j+1} - f_{j-1}}{2h}.$$

- In order to achieve spectral accuracy of the derivative, we can differentiate the spectral approximation:

## Spectrally-accurate finite-difference derivative

$$f'(x) \approx \phi'(x) = \frac{d}{dx} \phi(x) = \frac{d}{dx} \left( \sum_{k=0}^{N-1} \hat{f}_k e^{ikx} \right) = \sum_{k=0}^{N-1} \hat{f}_k \frac{d}{dx} e^{ikx}$$

$$\phi' = \sum_{k=0}^{N-1} \left( ik \hat{f}_k \right) e^{ikx} = \mathcal{F}^{-1} \left( i \hat{\mathbf{f}} \square \mathbf{k} \right)$$

- Differentiation becomes multiplication in Fourier space.**

# Unmatched mode

- Recall that for even  $N$  there is one unmatched mode, the one with the highest frequency and amplitude  $\hat{f}_{N/2}$ .
- We need to choose what we want to do with that mode; see notes by S. G. Johnson (MIT) linked on webpage for details:

$$\phi(x) = \hat{f}_0 + \sum_{0 < k < N/2} \left( \hat{f}_k e^{ikx} + \hat{f}_{N-k} e^{-ikx} \right) + \hat{f}_{N/2} \cos\left(\frac{Nx}{2}\right).$$

This is the unique “**minimal oscillation**” trigonometric interpolant.

- Differentiating this we get

$$\widehat{(\phi')}_k = \hat{f}_k \begin{cases} 0 & \text{if } k = N/2 \\ ik & \text{if } k < N/2 \\ i(k - N) & \text{if } k > N/2 \end{cases}.$$

- Real valued interpolation samples result in **real-valued**  $\phi(x)$  for all  $x$ .

# FFT-based differentiation

```
% From Nick Trefethen's Spectral Methods book
% Differentiation of  $\exp(\sin(x))$  on  $(0, 2\pi]$ :
N = 8; % Even number!
h = 2*pi/N; x = h*(1:N)';
v = exp(sin(x)); vprime = cos(x).*v;
v_hat = fft(v);
ik = 1i*[0:N/2-1 0 -N/2+1:-1]'; % Zero special mode
w_hat = ik .* v_hat;
w = real(ifft(w_hat));
error = norm(w-vprime, inf)
```

# The need for wavelets

- Fourier basis is great for analyzing periodic signals, but is not good for functions that are **localized in space**, e.g., brief bursts of speech.
- Fourier transforms are not good with handling **discontinuities** in functions because of the Gibbs phenomenon.
- Fourier polynomials **assume periodicity** and are not as useful for non-periodic functions.
- Because Fourier basis is not localized, the highest frequency present in the signal must be used everywhere: One cannot use **different resolutions in different regions of space**.

# An example wavelet

# Wavelet basis

- A **mother wavelet function**  $W(x)$  is a localized function in space. For simplicity assume that  $W(x)$  has compact support on  $[0, 1]$ .
- A **wavelet basis** is a collection of **wavelets**  $W_{s,\tau}(x)$  obtained from  $W(x)$  by **dilation** with a **scaling factor**  $s$  and **shifting** by a **translation factor**  $\tau$ :

$$W_{s,\tau}(x) = W(sx - \tau).$$

- Here the scale plays the role of frequency in the FT, but the shift is novel and localized the basis functions in space.
- We focus on **discrete wavelet basis**, where the scaling factors are chosen to be powers of 2 and the shifts are integers:

$$W_{j,k} = W(2^j x - k), \quad k \in \mathbb{Z}, j \in \mathbb{Z}, j \geq 0.$$

# Haar Wavelet Basis

# Wavelet Transform

- Any function can now be represented in the wavelet basis:

$$f(x) = c_0 + \sum_{j=0}^{\infty} \sum_{k=0}^{2^j-1} c_{jk} W_{j,k}(x)$$

This representation picks out frequency components in different spatial regions.

- As usual, we truncate the basis at  $j < J$ , which leads to a total number of coefficients  $c_{jk}$ :

$$\sum_{j=0}^{J-1} 2^j = 2^J$$

# Discrete Wavelet Basis

- Similarly, we discretize the function on a set of  $N = 2^J$  equally-spaced nodes  $x_{j,k}$  or intervals, to get the vector  $\mathbf{f}$ :

$$\mathbf{f} = c_0 + \sum_{j=0}^{J-1} \sum_{k=0}^{2^j-1} c_{jk} W_{j,k}(x_{j,k}) = \mathbf{W}_j \mathbf{c}$$

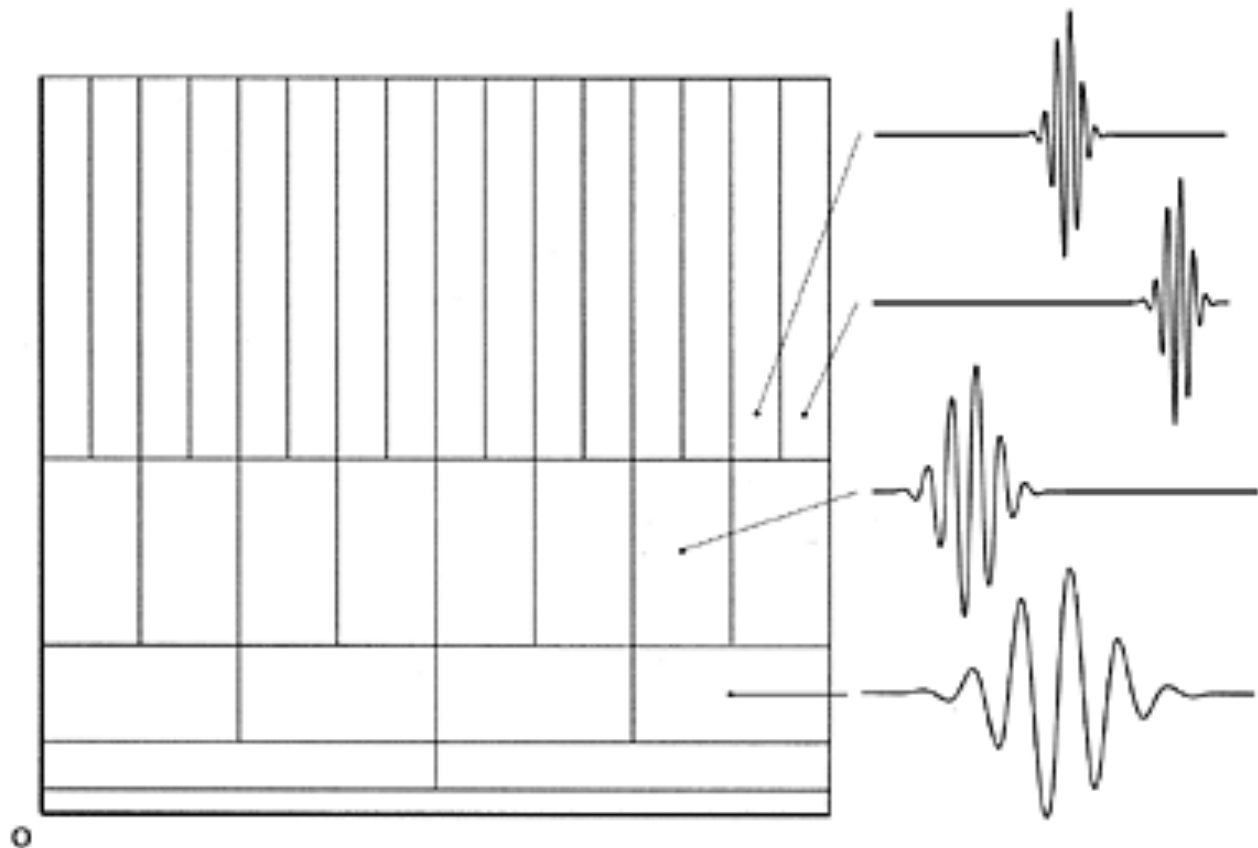

- In order to be able to quickly and stably compute the coefficients  $\mathbf{c}$  we need an **orthogonal wavelet basis**:

$$\int W_{j,k}(x) W_{l,m}(x) dx = \delta_{j,l} \delta_{k,m}$$

- The Haar basis is discretely orthogonal and computing the transform and its inverse can be done using a **fast wavelet transform**, in **linear time**  $O(N)$  time.

# Discrete Wavelet Transform

# Scaleogram

# Another scaleogram

# Conclusions/Summary

- **Periodic functions** can be approximated using basis of **orthogonal trigonometric polynomials**.
- The Fourier basis is **discretely orthogonal** and gives **spectral accuracy** for smooth functions.
- Functions with discontinuities are not approximated well: **Gibbs phenomenon**.
- The **Discrete Fourier Transform** can be computed very efficiently using the **Fast Fourier Transform** algorithm:  $O(N \log N)$ .
- FFTs can be used to **filter** signals, to do **convolutions**, and to provide spectrally-accurate **derivatives**, all in  $O(N \log N)$  time.
- For signals that have different properties in different parts of the domain a **wavelet basis** may be more appropriate.
- Using specially-constructed **orthogonal discrete wavelet basis** one can compute **fast discrete wavelet transforms** in time  $O(N)$ .
